AERODYNAMIC LOADINGS ASSOCIATED WITH SWEPT AND UNSWEPT
SPOILERS ON A FLAT PLATE AT MACH NUMBERS OF 1.61 AND 2.01

By Douglas R. Lord and K. R. Czarnecki

SUMMARY

An investigation has been made at Mach numbers of 1.61 and 2.01 for a range of Reynolds numbers from 0.12×10^6 to 0.56×10^6 per inch to examine the flow, force, and moment characteristics associated with spoilers mounted on a flat plate at sweep angles from 0° to 75° . The three basic spoilers included two inclined 90° and one inclined 45° to the flat-plate surface on which they were mounted. Pressure measurements were obtained over the plate and spoiler faces. These pressures were then integrated to determine the spoiler lift, pitching-moment, drag, and hinge-moment characteristics.

For the unswept condition, the pressure distributions along the plate and on the spoiler faces and the force and moment characteristics of the spoilers could be correlated for a given Mach number on the basis of the height and location of the spoiler top. The three-dimensional behavior of the flow over the swept spoilers and the limited data available precluded the establishment of any simple method for extending the unswept-spoiler results to the swept case. Regions of reversal in lift effectiveness and large decreases in pitching moment were observed near the spoiler apex for the swept spoilers. The section drag and hinge moments of the spoiler decreased as distance from the apex of the swept spoilers increased. Within the ranges of the tests, varying the Reynolds number or fixing transition generally caused only small changes in pressures or integrated characteristics.

INTRODUCTION

Among the many devices for providing control of aircraft at supersonic speeds, one of the most promising from the standpoint of low wing twist and low hinge moments is the spoiler. At the present time, however, there is available only a limited amount of data on such configurations. Force tests have been made on several small-scale models (refs. 1 to 4).

CONFIDENTIAL

56AA 12569

to determine the effects of spoiler size and location on the effectiveness obtained on wings of various plan forms. Pressure-distribution tests have also been made (refs. 5 to 8) in order to better understand the flow phenomena involved.

The data available indicate that there may be large changes in the aerodynamic characteristics of spoilers due to changing the sweep angle with respect to the air stream. In an attempt to obtain a more fundamental insight into the flow field of a swept spoiler, pressure-distribution measurements have been made in the vicinity of and on several spoilers mounted on a flat plate. The tests were made on a flat plate rather than on a wing because fundamental correlations and theoretical analyses could be obtained more easily and it circumvents the complex flow field of an actual wing with its chordwise pressure gradients and spanwise boundary-layer flows. It should be mentioned that this is a basic first step and the application of the results to actual wing spoiler installations will require further study. In the present report, the effect of sweeping spoilers through an angle range from 0° to 75° in a uniform flow field having a turbulent boundary layer at Mach numbers of 1.61 and 2.01 has been studied. In addition to the effects of sweep and Mach number, the effects of spoiler height, inclination, and span were investigated as were the effects of fixing transition, simulated actuating arms, and an endplate. The Reynolds number range was from 0.12×10^6 to 0.56×10^6 per inch and the maximum spoiler height was 0.896 inch. Some preliminary results of these data were reported in reference 9.

SYMBOLS

M	stream Mach number
β	$\sqrt{M^2 - 1}$
R	Reynolds number per inch
q	stream dynamic pressure
p	stream static pressure
p_l	local surface pressure
c_p	pressure coefficient, $\frac{p_l - p}{q}$

- x streamwise distance from base of spoiler front face along given orifice row
- y distance from upstream tip of spoiler along spoiler
- z perpendicular distance from bypass plate
- h spoiler height (distance from base to top of spoiler measured perpendicular to the bypass plate; see fig. 1)
- c_s spoiler chord (distance from base to top of spoiler measured along spoiler face; see fig. 1)
- c hypothetical wing chord determined by length of orifice row
- δ spoiler deflection angle (angular displacement of spoiler about base with respect to bypass plate; see fig. 1)
- Λ spoiler sweep angle (angular displacement of spoiler parallel to bypass plate, with respect to a plane perpendicular to the stream; see fig. 1)
- l section lift produced by spoiler over the distance c
- m section pitching moment of l about spoiler base
- d section drag of spoiler (streamwise)
- h' section hinge moment of spoiler about spoiler base
- c_l section lift coefficient, $\frac{l}{q_h}$
- c_m section pitching-moment coefficient, $\frac{m}{q_h^2}$
- c_d section drag coefficient, $\frac{d}{q_h}$
- $c_{h'}$ section hinge-moment coefficient, $\frac{h'}{q c_s^2}$
- c_l' section lift coefficient, $\frac{l}{q_c}$
- c_m' section pitching-moment coefficient, $\frac{m}{q c^2}$

APPARATUS,

Wind Tunnel

This investigation was conducted in the Langley 4- by 4-foot supersonic pressure tunnel which is a rectangular, closed-throat, single-return type of wind tunnel with provisions for the control of the pressure, temperature, and humidity of the enclosed air. Flexible nozzle walls were adjusted to give the desired test-section Mach numbers of 1.61 and 2.01. During the tests, the dewpoint was kept below -20° F so that the effects of water condensation in the supersonic nozzle were negligible.

Model and Model Mounting

The models used in this investigation consisted of several spoilers mounted on a boundary-layer bypass plate as shown in figure 1. The three basic spoilers are shown as configurations 2, 3, and 4 in figure 2. (Configuration 1 is not shown, since by test nomenclature it was the no-spoiler condition.) As modifications were made to the basic models, they were assigned the subsequent configuration numbers 5 through 9 as shown in figure 2. Each spoiler was constructed of steel with the pressure-tube installations made in grooves in the surfaces which were faired over with a transparent plastic material. The 22 spoiler orifices were located at two stations along the span on the front and rear faces of the spoiler as described in the table of figure 2.

The turntable on which the spoilers were mounted was installed flush with the boundary-layer bypass plate as shown in the photographs of figure 3. This turntable was instrumented with 265 pressure orifices located in seven rows as described in figure 2 and tables 1 through 22. The numbering system used to identify the six rows passing through station 1 was chosen to immediately identify the angle of the row with respect to the stream. Thus, the first digit of the angular displacement of each row from the basic row 0 identifies the row. For $\Lambda = 0^\circ$, then, row 0 is parallel to the stream, for $\Lambda = 15^\circ$, row 1 is parallel to the stream, for $\Lambda = 30^\circ$, row 3 is parallel to the stream, etc. Note that row 9 is a shorter row parallel to row 0 but passing through station 2. There were no pressure orifices on either the endplate or the actuating arms.

TESTS

The model sweep angle was varied by rotating the turntable in the bypass plate and was measured by a vernier on the outside of the tunnel. The pressure distributions were determined from photographs of the multiple-tube manometer boards to which the pressure leads from the

spoiler and turntable orifices were connected. The reduction of the data to pressure-coefficient form and the integration of the pressure distributions along the plate by a step integration procedure were performed by IBM equipment. The integration of the pressure distributions over the spoiler faces was performed with mechanical integrators.

The majority of the tests were made at sweep angles from 0° to 75° in intervals of 15° so that a row of tubes on the plate was always aligned with the stream. Configuration 5 was tested at $\Lambda = 45^\circ$ only and configuration 8 was tested at both positive and negative sweep angles. Most of the tests were made at tunnel stagnation pressures of 13 and 15 pounds per square inch at Mach numbers of 1.61 and 2.01, respectively, corresponding to a Reynolds number of 0.30×10^6 per inch. Additional tests were made on some configurations in which the stagnation pressure was varied. The maximum Reynolds number range covered was from 0.14×10^6 to 0.56×10^6 per inch at $M = 1.61$ and from 0.12×10^6 to 0.30×10^6 per inch at $M = 2.01$. All of the tests except those of configuration 6 were made under conditions of fixed transition using a 1/4-inch strip of No. 60 carborundum attached to the boundary-layer bypass plate 1 inch from its leading edge. (See fig. 1.)

PRECISION

The mean Mach numbers in the region occupied by the model are estimated from calibrations to be 1.61 and 2.01 with local variations being smaller than ± 0.02 . There is no evidence of any significant flow angularities. The estimated accuracy in setting the spoiler sweep angle is $\pm 0.05^\circ$. The basic measured quantity C_p is believed accurate to ± 0.01 .

RESULTS

The complete pressure-distribution results of this investigation are presented in tables 1 to 22. The analysis of the data and presentation of the figures is made in four sections: first, the pressures measured on the turntable (figs. 4 to 14); second, the pressures measured on the spoiler faces (figs. 15 to 24); third, the integrations of the turntable pressures along streamwise rows to determine section lift and pitching moments caused by the spoilers (figs. 25 to 29); and fourth, the integrations of the spoiler-face pressures to determine the spoiler drag and hinge moments (figs. 30 to 34).

DISCUSSION

Plate Pressures

Effect of sweep. - The basic data from the plate pressures, measured by use of the turntable orifices, are presented in figure 4 in the form of streamwise pressure distributions at station 1 through the sweep-angle range from 0° to 75° . At $\Lambda = 0^\circ$, the pressure distributions show the same general shapes as were shown in the tests of reference 7. In order to surmount the spoiler, the flow must be deflected from the plate surface some distance ahead of the spoiler causing a shock and the associated rapid pressure rise. The pressure then remains relatively constant until a point is reached just forward of the spoiler base, where a second pressure increase occurs due to stagnation of the circulatory flow in the wedge-shaped separated-flow region ahead of the spoiler. A rapid expansion to a negative pressure coefficient occurs at the top of the spoiler, followed by a gradual compression back to stream pressure some distance downstream of the spoiler.

When the spoiler is swept with respect to the stream, the flat portion of the pressure distribution ahead of the spoiler between the two compression regions is gradually replaced by a region of accelerated flow. This is in agreement with the data of reference 6, which considered only the distributions ahead of the spoiler. The mechanics of the flow causing this acceleration is not fully understood, but is believed to be caused by the three-dimensional nature of the flow for the swept condition. As was previously described in reference 9, the flow not only must be deflected by a shock from the surface to surmount the spoiler height, but also must be turned along the plate surface by a new shock; thus allowing the flow to move parallel to the face of the spoiler. The first of the two shocks would tend to remain close to and parallel to the spoiler; whereas the second shock would tend to assume the position of a detached shock wave about the apex of the spoiler with the shock angle decreasing along the span to the Mach angle at an infinite distance. The interaction of the two shocks, then, determines the location and strength of the first compression on the pressure distributions. At some distance from the apex the two shocks tend to separate and a region of accelerated flow appears between them. This acceleration may be due to the relieving effect of the flow passing over the spoiler similar to the relieving effect experienced within the Mach cone near a wing tip. (Consider the bypass plate as a reflection plane and the spoiler as a low-aspect-ratio wing at a very high angle of attack.)

Downstream of the spoiler, the pressure distribution tends to change from a triangular to a rectangular loading as the sweep is increased. At the largest sweep angle of 75° , which is probably a more academic

than practical condition, the pressure distribution downstream of the spoiler becomes erratic and the loading is generally very small.

In order to investigate in more detail the changes in the flow field with changes in sweep angle, configuration 8 was tested at positive and negative sweep angles. By superimposing the contour plots obtained from all the pressures measured on the plate at reversed angular conditions, the contour plots of figure 5 were obtained and show much more of the field than would the two-quadrant coverage at the positive angles alone.

At $\Lambda = 0^\circ$, figure 5(a) shows the symmetry of the flow and the relieving effect of the spoiler tips. Over the largest portion of the spoiler span the flow is essentially two-dimensional. When the spoiler is swept, the remainder of figure 5 shows the development of the three-dimensional flow field over the entire spoiler span. The upstream influence of the spoiler generates a pressure field which assumes the shape of a detached shock about the spoiler apex. The largest accelerations ahead of the spoiler occur in a region approximately parallel to the spoiler and the largest compressions just ahead of the spoiler occur near the apex. Behind the spoiler, the expansion from the apex becomes evident at the higher sweep angles ($\Lambda = 45^\circ$) and the shape of the isobars indicates the presence of vortices in the approximate direction of the stream. Since the spoiler can be considered to be a very low-aspect-ratio wing, the formation of tip vortices due to the pressure differential across the spoiler would confirm these indications. At $\Lambda = 75^\circ$, it was impossible to obtain contours downstream of the spoiler due to asymmetries in the spoiler support (see fig. 1) which caused asymmetries in the pressure contours at $\Lambda = \pm 75^\circ$.

From the previous discussion of the three-dimensional character of the flow over a swept spoiler, it becomes obvious that a complete analysis of the effects of sweep on a spoiler would be incomplete without pressure surveys over the complete span of the spoiler. Figure 6(a) shows the systematic changes in the pressure distributions as two successive portions of the tip of configuration 2 were removed - the pressure-distribution station therefore approaching more closely the spoiler apex. Figure 6(b) shows similarly the effect of 0° , 30° , and 60° of sweep on the pressure distributions measured in the streamwise direction at five different distances from the spoiler apex in terms of the spoiler height. At the closest station to the apex ($y/h = 4.3$), $\Lambda = 60^\circ$ has the least forward effect; whereas at the furthestmost station from the apex ($y/h = 11.7$), $\Lambda = 60^\circ$ has the most forward effect. The change takes place in a gradual and consistent manner as y/h increases.

Effect of spoiler height. - The effects on the pressure distributions of decreasing the spoiler height from 0.896 inch for configuration 2 to 0.586 inch for configuration 3 are shown in figure 7. The abscissa

is the distance in spoiler heights and the pressure distributions at $\Lambda = 0^\circ$ show excellent correlations on this basis. At the sweep angles considerable differences become evident; however, these are probably due primarily to the difference in location of the pressure station from the spoiler apex in terms of the height. Thus, the pressure distributions for configuration 3 are affected by the initial compression further forward because the measuring station for configuration 3 is further outboard from the apex, in spoiler heights.

Effect of spoiler deflection angle.- The effect on the pressure distributions of decreasing the spoiler deflection angle from 90° for configuration 2 to 45° for configuration 4 is shown in figure 8. In this figure the abscissa has been chosen as the distance from the top of the spoiler in heights because it was anticipated that the position of the top of the spoiler would dictate the pressure distribution along the plate. That this was the case can be seen from the good correlation obtained for the unswept spoiler condition. At sweep angles the differences obtained are again due to varying distances from the spoiler apex in heights and are therefore inconclusive in considering the effect of deflection angle.

If the practical applications of configurations 2 and 4 as a hinged spoiler are considered, it is of interest to plot the pressure distributions in terms of some given wing chord as has been done in figure 9. The comparison then shows the pressure distributions on a fictitious flat-plate wing having a flap-type spoiler deflected to 90° and 45° . Ahead of the spoiler the half-deflected spoiler carries about 60 percent of the load of the fully deflected one. Behind the spoiler there is little change in the pressure distribution due to increasing the spoiler deflection from 45° to 90° . It should be mentioned that the 45° spoiler is carrying some lifting load on the spoiler itself, which is not accounted for here.

Effect of simulated actuator arms.- Although the choice of location and shape of the simulated actuator arms is completely arbitrary, they should be satisfactory for investigating the effect of such protuberances from the front face of the spoiler. In figure 10, comparison is made between the pressure distributions obtained on configuration 3 (without actuator arms) and those obtained on configuration 9 (with actuator arms). At $\Lambda = 0^\circ$ and 15° , where little spanwise flow is present, no effect of the actuator arms is evident. As the sweep is increased, the effect of the arms increases until at 75° a very sharp compression region occurs, followed by a very sharp expansion region, some distance ahead of the spoiler along the orifice row. Here again the inherent weakness of the test technique involving a measurement at only one spanwise station is evident. At the larger sweep angles, the rows of orifices being used are closer to the actuating arm and, therefore, the sudden variations may be present in only a localized area near each actuator arm due to the interruption of the spanwise flow.

Effect of Mach number. - Although the Mach number range of these tests was limited, it is of interest to consider the effect of Mach number and the predictability of that effect. Figure 11 shows for three sweep angles a comparison of the streamwise-pressure distributions on configuration 2 at the two test Mach numbers. In addition, the similar variations are shown for the normalized pressure distributions using

the $\beta = \sqrt{M^2 - 1}$ relationship. The basic pressure distributions show generally decreased loadings due to increasing Mach number, as would be expected, except near the spoiler at $\Lambda = 60^\circ$. The β relationship, shown to be effective in predicting pressure distributions on flap-type controls in reference 10, failed to correlate the pressures measured ahead of the spoiler, but did fairly well in correlating the pressures measured downstream of the spoiler. This result is not unexpected. The flow behind the spoiler is similar to the flow at the base of a body or behind the thick trailing edge of a wing for which the base pressure is well known

to vary approximately as $1/\sqrt{M^2 - 1}$. (For example, see ref. 11.) The pressures in front of the spoiler are dependent upon pressure rise required to separate a turbulent boundary layer. No theory for calculating the general pressure distribution is available, but the variation of the first pressure rise with Mach number at zero sweep is in good agreement with the theoretical predictions of reference 12 and the experimental results of references 7 and 13.

Effect of Reynolds number. - The effect on the pressure distributions of increasing the Reynolds number from 0.14×10^6 to 0.56×10^6 per inch is shown in figure 12. The only appreciable effect of Reynolds number appears to be in the region of the first compression. This is the most inaccurate portion of the pressure distribution due to the rapid changes in pressure and fewer number of orifices.

Effect of fixing transition. - The pressure distributions showing the effects of fixing transition at $R = 0.30 \times 10^6$ and 0.14×10^6 are shown in figure 13. The results at $R = 0.30 \times 10^6$ show no effect throughout the sweep-angle range. At $R = 0.14 \times 10^6$, preliminary investigation of the data indicated some effect at station 1 and a greater effect at station 2. Since the streamwise rows are not available at station 2, for figure 13(b), the effect of fixing transition has been shown along the rows perpendicular to the spoiler at the two stations for sweep angles of 0° , 30° , and 60° . Indications are that in the natural transition case the flow at this low Reynolds number has not become fully turbulent when the region of influence of the spoiler is first reached. The reason for the effect being greater at station 2 probably results from the shorter run along the bypass plate from the leading edge due to the leading-edge sweepback. By the time $\Lambda = 60^\circ$ is reached, the effect of fixing transition has disappeared.

Effect of the endplate.- The basic streamwise pressure distribution at station 1 for configuration 5, which used the same spoiler as configuration 2 with the addition of the endplate, is shown in figure 14 compared with configuration 2. The changes due to the endplate are small and it would therefore appear that the flow at this station is little influenced by a fuselage-type endplate aligned with the stream. Inspection of the pressure contours indicates that there are only small changes ahead of the spoiler across the span due to installation of the endplate.

Spoiler Pressures

Effect of sweep.- The basic data from the spoiler pressures, measured by use of the spoiler-face orifices, are presented in figure 15 in the form of pressure distributions, from bottom to top of the spoiler, through the sweep-angle range from 0° to 75° . For the unswept condition there is very little difference between the pressure distributions measured at station 1 and those measured at station 2. All of the configurations, except configuration 4, were perpendicular to the plate and exhibit similar distributions. The pressures are generally constant over the rear face; however, the pressures over the front face indicate stagnation regions near the bottom and top of the spoiler such as were described in reference 13. These are attributed to the circulatory flow in the separated region ahead of the spoiler. On configuration 4, which is deflected only 45° to the plate, the distribution on the front face is considerably different, there being no stagnation point near the bottom, the largest pressure occurring at about 80 percent of the height and being followed by an acceleration. Consideration of the shape of the circulatory flow region for this configuration indicates that the shallow angle through which the reversed flow must turn at the base mitigates the pressure increase previously noted for the 90° spoiler. Near the top of the 45° spoiler, in contrast, the flow must reverse through an angle approaching 180° , which it apparently finds impossible to negotiate and therefore loses some of the circulating air over the top of the spoiler.

As the spoiler is swept, the loadings on both surfaces of the spoiler tend to decrease, but in a manner other than linear. The stagnation areas at the top and bottom of the 90° spoiler front faces gradually disappear until at $\Lambda = 60^\circ$ and 75° the distributions along the front faces of the 90° and 45° deflected spoilers are identical. For many of the swept conditions there are large differences in the distributions at the two spanwise stations, both on the rear and front faces. As would be expected from the previous discussion of the pressures on the plate, the spoiler face pressures are directly controlled by the angle of sweep and proximity to the spoiler apex. It should be noted that a good approximation of the average loads on the spoiler can be obtained by assuming the plate pressures ahead of and behind the spoiler to apply uniformly over the adjacent spoiler faces. This has been shown previously in references 14 and 9.

In order to consider in more detail the spanwise variations in spoiler face pressures, the front-face pressure-coefficient contours and variations across the span of the pressure coefficient at constant z/h have been presented in figure 16. These plots were obtained by superimposing the pressures measured on configurations 2, 7, and 8, which gave a total of 6 spanwise locations of a spoiler orifice station with respect to the spoiler apex. The contour plots of figure 16(a) show the two-dimensionality of the flow over the unswept spoiler and the large spanwise variations for the swept conditions. The most pronounced change occurs between the sweep angles of 45° and 60° where the stagnation regions disappear and the acceleration near the top appears. The contour plots for the rear face are not presented because of the small pressure changes involved which make the contours more inaccurate. The variations across the span of the pressures at the bottom, middle, and top of the spoiler faces, presented in figure 16(b), show that for sweep angles from 30° through 60° the loadings near the apex of the spoiler are much greater than those further from the apex. This is the same effect as has been previously demonstrated transonically by the tests of reference 12. At a sweep angle of 75° , the pressures over the rear face are so erratic that it is impossible to fair curves through the points. The dissimilarity of the variations measured at the two stations indicates that at this large sweep angle the differences in the spoiler support are responsible for these changes.

In figure 6, the systematic variations of the streamwise pressure distribution due to removal of portions of the tip of the spoiler, equivalent to movement along the span, were shown. Similarly, in figure 17, cutting off the tip of the spoiler at sweep angles from 30° through 60° causes gradual increases in the spoiler loadings on both surfaces and moving along the span from $y/h = 4.3$ to $y/h = 11.3$ causes a systematic change in the variation of the spoiler-face pressure distributions with sweep angle.

Effect of spoiler height. - The effect of spoiler height on the spoiler-face pressure distributions is shown by figure 18 to be negligible at 0° sweep but considerable at many sweep angles. The reduced loading for the smallest swept spoiler is probably a result of the larger distance in heights of the measuring station from the apex. The decrease in spoiler loading as distance from the apex increases has been previously discussed. It therefore appears that, for a given span swept spoiler, the shorter the spoiler height, the smaller will be the span affected by the apex.

Effect of spoiler deflection angle. - The effect of spoiler deflection angle, δ , on the spoiler-face pressure distributions has already been discussed in some detail. A direct comparison is shown, however, in figure 19. For sweep angles from 0° to 45° the average loadings for the two configurations are very similar although the variations over the

front face are different due to the differences in circulation described previously. At $\Lambda = 60^\circ$ and 75° , the variations over the faces are similar, but now the loadings on the $\delta = 45^\circ$ spoiler tend to decrease due to the greater distance of the measuring station from the apex, in actual spoiler heights.

Effect of simulated actuator arms. - The effect of the simulated actuator arms on the spoiler-face pressure distribution is shown in figure 20. At $\Lambda = 0^\circ$ and 15° , there is little effect, as would be expected, because of the small cross flows present for these angles. At larger sweep angles, the actuator arms may be considered as secondary spoilers, presenting obstructions to the spanwise flow along the front spoiler face. As a result, the face pressures at station 1, which is $1\frac{1}{4}$ inches ahead of an actuator arm, are increased.

Effect of Mach number. - The effect on the spoiler-face pressure distributions of increasing the Mach number from 1.61 to 2.01 is shown in figure 21. The effects are similar to those previously shown for the plate pressures. The loadings on both spoiler faces decrease with increasing Mach number except for the front face at $\Lambda = 60^\circ$. The correlation of the pressure distributions with the β relationship is excellent on the rear face but poor on the front face.

Effect of Reynolds number. - The effect on the spoiler-face pressure distributions of increasing the Reynolds number from 0.14×10^6 to 0.56×10^6 per inch is shown in figure 22. The localized variation with Reynolds number of the pressures near the top of the front face at $\Lambda = 30^\circ$ could have been caused by malfunction of one pressure orifice and is therefore questionable. In general, the variations due to Reynolds number are small and within the repeatability of the test results.

Effect of fixing transition. - The effect of fixing transition on the spoiler-face pressure distributions is shown in figure 23. At $R = 0.30 \times 10^6$ (fig. 23(a)), the effect is negligible. At $R = 0.14 \times 10^6$ (fig. 23(b)), there is some change due to fixing transition on the front-face pressures at $\Lambda = 0^\circ$ and 30° . The greatest effect is found at station 2 and is believed to be caused by the failure of the boundary layer to become fully turbulent for the natural transition case at this low Reynolds number, as has been previously discussed.

Effect of the endplate. - The basic spoiler-face pressure distributions for configuration 5 are shown in figure 24 compared with the pressure distributions for configuration 2. The largest differences are shown on the front face at station 1 and on the rear face at station 2. Here again the lack of sufficient spanwise-measuring stations prevents a detailed analysis and an understanding of the effect of the endplate on the flow field of the spoiler.

Plate Spoiler Lift and Pitching Moments

Effect of sweep. - The basic lift and pitching-moment coefficients, determined from integration of the streamwise plate-pressure distributions, and including the contributions of the load on the spoiler, are presented in figures 25 and 26, respectively. It should be remembered that, for the largest sweep angles tested, the integrations do not give the total lift and pitching moment developed by the spoiler because the pressure orifices did not extend far enough to cover the complete region affected. Also, the integrated characteristics were obtained for streamwise rows through station 1 only; therefore, for a given configuration, they will not necessarily be representative of the characteristics at other stations. Despite these limitations, the changes with sweep and other test conditions will be of interest.

When a spoiler is deflected on the upper surface of the wing, as, it is assumed, are the spoilers in these tests, a negative lift is desired. For the unswept conditions, the total lift for all the configurations tested here is negative, despite the positive lift caused by the pressures downstream of the spoiler. When the spoilers are swept, the gradual decrease in negative lift ahead of the spoiler and the often-times abrupt increase in positive lift behind the spoiler near $\Lambda = 45^\circ$ causes the total lift to become positive near $\Lambda = 45^\circ$. Above $\Lambda = 60^\circ$ the positive lift behind the spoiler decreases rapidly; however, the negative lift ahead of the spoiler has been almost eliminated so that the total lift approaches zero. Note that, for the $\delta = 45^\circ$ spoiler (configuration 4), much of the negative lift is carried by the spoiler itself.

Because of the strong positive lift experienced behind the spoiler, the most efficient location on a wing for a negative lift-producing spoiler is at the trailing edge. The advantage of trailing-edge spoilers for lift or roll control has long been recognized and has been discussed in references 1, 2, 3, 5, and 6.

The pitching-moment coefficients of figure 26 have been computed about the spoiler base; therefore, the loadings ahead of and behind the spoiler cause negative pitching moments, resulting in a negative total pitching-moment coefficient throughout the sweep-angle range. For most of the configurations, the pitching-moment contribution of the loading ahead of the spoiler shows gradual and small changes with increasing sweep. This is apparently due to the counterbalancing effects of the decreasing lift with the forward movement of the center of pressure of that lift. The pitching-moment contribution of the loading behind the spoiler shows a very rapid increase due to both the increasing lift and the rearward movement of the center of pressure of that lift. The pitching-moment contribution due to the loading on the spoiler is always positive and small. As a result of these variations of the loading

components, the total pitching-moment coefficient generally increased negatively with increasing sweep angle to a peak near $\Lambda = 60^\circ$ and then decreased rapidly toward zero.

Now to examine by direct comparison the effect of configuration and test-condition changes on the integrated coefficients, the lift- and pitching-moment coefficient variations with sweep angle showing most of the effects being considered are shown in figure 27. The effect of the proximity of the apex to the measuring station is demonstrated by superimposing the curves for configurations 2, 7, and 8. As the spoiler tip is cut off, the distance from the station to the apex decreases. At low sweep angles, the negative lift decreases with decreasing distance from the apex. It therefore appears that, in regions near the apex of, say, a 45° swept spoiler, regions of reversed lift effectiveness may be encountered. Such regions of reversal can be seen in the span load distributions of reference 14. The importance of reversed lift in this region will depend to a great extent on the spoiler height-span ratio.

The effect on the pitching moment of removing portions of the tip is considerably greater than that on the lift (fig. 27(b)). Closer to the apex, the negative moments are decreased considerably and the hump in the moment variation with Λ at large sweep angles is eliminated.

Effect of fixing transition.- The comparison of the lift- and pitching-moment coefficient variations with sweep angle for configurations 2 and 6 (fig. 27) shows that the effect of fixing transition at this Reynolds number is negligible.

Effect of spoiler height.- The comparison of the lift- and pitching-moment-coefficient variations with sweep angle for configurations 2 and 3 shows small changes in the lift but large changes in pitching moment due to decreasing the spoiler height. The similarity of the lift curves is somewhat surprising considering the relative distances, in heights, from the apex to the measuring station for the two configurations. It may be that for the swept conditions the reduced pressures ahead of the spoiler, as spanwise distance from the apex increases, are balanced by the increase in streamwise distance over which the pressures occur so that the integrated lift shows little change. The large moment effect is caused by the relative location of the initial compression to the spoilers and the relative extent of the orifice row downstream in terms of their spoiler heights (see fig. 7). For the two spoilers, the location of the initial disturbance in the swept condition is at approximately the same place on the plate which makes it much further forward of the small spoiler, in heights.

Effect of spoiler deflection angle.- In order to show the effect of deflection angle, δ , on the lift and pitching moments, configurations 3

and 4 have been compared (fig. 27) because the heights are more nearly equal than those of configurations 2 and 4. The lift produced by configuration 3 is somewhat more negative than that of configuration 4 over most of the sweep-angle range. The pitching-moment coefficients show considerable effect of deflection angle since it was previously shown that the location of the spoiler top determined the pressure distribution.

In order to consider the practical application of a flap-type spoiler on a hypothetical wing, figure 28 presents the total lift and pitching-moment coefficients, based on a given wing chord for configurations 2 and 4 for which $\delta = 90^\circ$ and 45° , respectively. This comparison then shows the change in lift and pitching moment caused on a given wing by a flap-type spoiler deflected from 45° to 90° . At all sweep angles, the lift and pitching moment is increased by increasing δ from 45° to 90° . At sweep angles below 30° , the $\delta = 45^\circ$ spoiler produces more than half the negative lift that the $\delta = 90^\circ$ spoiler produces. At sweep angles over 15° , the $\delta = 45^\circ$ spoiler produces more than half the pitching moment that the $\delta = 90^\circ$ spoiler produces, and at $\Lambda = 60^\circ$ it produces 80 percent as much moment. At small sweep angles, therefore, the half-deflected spoiler is a more efficient lift producer and at large sweep angles the half-deflected spoiler produces greater pitching moment per degree deflection angle.

Effect of actuator arms. - The effect on the integrated characteristics of the actuator arms (fig. 27) is to decrease the lift at sweep angles up to 40° and to increase the lift at higher angles; whereas the pitching moment is generally increased at sweep angles up to 55° and decreased at higher angles. These characteristics are probably true only at this station and similar stations with respect to the actuator arms and, therefore, are not indicative of the integrated effect across the span of such actuators.

Effect of Mach number. - Comparison of the lift and pitching moment for configuration 2 at the two test Mach numbers (fig. 27) indicates small changes in lift and fairly large decreases in pitching moment due to increasing the Mach number. At low sweep angles the lift is greatest at $M = 1.61$; whereas at large sweep angles, the lift is greatest at $M = 2.01$. These changes in lift and pitching moment are a direct result of the manner in which the loadings decreased due to increasing Mach number. (See fig. 11.)

Effect of the endplate. - The changes in lift and pitching moment at station 1 due to addition of the endplate at the spoiler apex are shown by figures 25 and 26 to be negligible.

Effect of Reynolds number. - The effect of Reynolds number on the lift and pitching-moment coefficients is shown in figure 29. There is no significant effect.

Spoiler Drag and Hinge Moments

Effect of sweep.— The basic drag and hinge-moment coefficients, determined from integration of the spoiler-face pressure distributions, are presented in figures 30 and 31, respectively. Unless specifically stated by y/h values or station number, the data presented in this entire drag and hinge-moment section were obtained at station 1.

In general, the total drag-coefficient variation with sweep angle (fig. 30) is very similar to that of the drag due to the pressures on the front face of the spoiler. For these curves the drag decreases with increasing sweep to values near zero at $\Lambda = 75^\circ$; however, the curves are at times erratic. The drag due to the rear face pressures, on the other hand, decreases very smoothly through the sweep-angle range. The front-face loading produces a greater proportion of the drag than does the rear-face loading except at some of the largest sweep angles.

The total hinge-moment-coefficient variation with sweep angle (fig. 31) also follows the trend of the hinge-moment coefficient due to the front face pressures, in general decreasing with increasing sweep, but reversing this trend over certain sweep-angle ranges on some configurations. The variation of hinge-moment coefficient with sweep angle for configuration 8 had the greatest changes. The hinge moment due to the rear-face pressure remained fairly constant over most of the sweep-angle range, decreasing at the highest values of Λ . The front-face loading produces a greater proportion of the hinge moment than does the rear-face loading except at some of the largest sweep angles.

To examine more closely the effect of configuration and test-condition changes on the drag and hinge moments, direct comparisons showing most of the effects investigated are presented in figure 32. The comparison of the drag and hinge moments for configurations 2, 7, and 8 shows that at $\Lambda = 0^\circ$ and 75° there is little change due to decreasing the distance from the apex. At the intermediate sweep angles, the drag and hinge moments become much greater as the distance from the apex is decreased. At $\Lambda = 45^\circ$, the hinge moment measured on configuration 8 is even greater than that measured at $\Lambda = 0^\circ$.

The decreasing load on the swept spoiler outboard from the apex is in agreement with the variation of the spoiler section-load parameter on the 45° swept wing of reference 14. It must be remembered, of course, that the tests of reference 14 were made on a tapered wing, and the spoiler projection was based on the local chord so that part of the decrease shown is due to the change in spoiler height along the span.

Since in the present tests two stations of pressures were available on each configuration, by using the integrated results at both stations on configurations 2, 7, and 8, it is possible to show the drag and hinge-moment variations over a fairly large range of distances from the apex, as shown in figure 33. It appears from these curves that the greatest variations across the span occur for a sweep angle near 45° . It is interesting to note that this is near the angle at which the spoiler becomes parallel to the Mach line ($\Lambda = 52^\circ$) at this Mach number. The greatest changes with sweep are found at the smallest values of y/h , or nearest the apex. The peaks of the hinge-moment curves due to the effect of the apex occur at higher values of Λ than do the peaks of the drag curves.

Effect of fixing transition. - The comparison of the drag- and hinge-moment coefficient variations with sweep angle for configurations 2 and 6 (fig. 32) shows that the effect of fixing transition at this Reynolds number is negligible, as would be expected from the previous discussions.

Effect of spoiler height. - The drag- and hinge-moment-coefficient comparisons (fig. 32) show that at $\Lambda = 0^\circ$ the effect of decreasing the spoiler height is to decrease both the drag and hinge-moment coefficients. When the spoiler is swept, the comparison of configurations 2 and 3 does not show the effect of height alone, due to the differences in distance from the apex in terms of the spoiler height. The comparison of the curves shows a continuation of the trend previously shown due to increasing y/h . (See fig. 33.)

Effect of spoiler deflection angle. - Increasing the spoiler deflection angle from 45° to 90° causes little change in the drag and hinge moment at sweep angles less than 30° . As the spoiler sweep angle is increased above 30° , the drag- and hinge-moment coefficients for configuration 4 are first larger and then smaller than those for configuration 5.

Effect of actuator arms. - The actuator arms have no effect on the drag and hinge moments measured at this station at $\Lambda = 0^\circ$ and 15° , as shown by the comparison of configurations 3 and 9 (fig. 32). At higher sweep angles, the actuator arms increase both the drag and hinge moments. As pointed out in previous discussions, this may be a localized effect.

Effect of Mach number. - The drag- and hinge-moment coefficient variations with sweep angle of configuration 2 at the two test Mach numbers (fig. 32) show the same general shapes. The differences due to Mach number are greatest at $\Lambda = 0^\circ$ and gradually decrease with increasing Λ . At the largest sweep angles investigated there is very little change due to Mach number.

Effect of the end plate. - The addition of the end plate at the spoiler apex is shown by figures 30 and 31 to cause increases in both

drag and hinge moment, primarily due to the change in pressures on the front face at this station. (See fig. 24.)

Effect of Reynolds number.- The changes in drag and hinge moment with increasing Reynolds number are illustrated in figure 34. For most of the angular conditions, no effect of Reynolds number is evident; however, at the smallest sweep angles, there is a definite trend showing some small increases with increasing Reynolds number.

CONCLUSIONS

An investigation has been made at Mach numbers of 1.61 and 2.01 to examine the flow, force, and moment characteristics associated with spoilers mounted on a flat plate at sweep angles from 0° to 75° . The results of the tests indicate the following conclusions:

1. For the unswept condition, the pressure distributions along the plate and on the spoiler faces, and the force and moment characteristics of the spoilers could be correlated for a given Mach number on the basis of the height and location of the spoiler top.
2. The three-dimensional behavior of the flow over the swept spoilers and the limited data available precluded the establishment of any simple method for extending the unswept-spoiler results to the swept case.
3. Regions of reversal in lift effectiveness and large decreases in pitching moment were observed near the spoiler apex for the swept spoilers.
4. The section drag and hinge moments of the spoiler decreased as distance from the apex of the swept spoilers increased.
5. The simulated actuator arms caused localized changes in the flow over the swept spoilers.
6. The simple $\sqrt{M^2 - 1}$ relationship, where M is the Mach number, was successful in predicting the effects of Mach number only on the pressures downstream of the spoiler.

7. Within the ranges of the tests, varying the Reynolds number from 0.12×10^6 to 0.56×10^6 per inch, or fixing transition generally caused only small changes in pressures or integrated characteristics.
